Abstract

This work is pertaining to the synthesis of fine magnesium aluminate spinel (MgAl_2O_4) powders of varied trivalent:bivalent cation ratio along line of homogeneity of the solid solution ($\text{MgO} \cdot x\text{Al}_2\text{O}_3$, $x=1, 1.25, 1.50, 1.75, \text{ and } 2$) via gel combustion method. Magnesium- and aluminum- nitrate were used as the oxidants in combustion reaction fuelled by urea in combination with stoichiometric formaldehyde solution acting as reductant. Synthesized powders were characterized in terms of microscopic analysis and optical absorbance measurements. The cation ratio, through a change in gel structure influences the nature of crystallization of the product, while on the other hand does not affect grain shapes and sizes. Distinct enhancement in both absorption intensity and the corresponding estimated energy band gap has been observed against increasing excess than stoichiometric alumina concentrations. Evaluated optical band gaps were widened in proportion to the Al: Mg ratio which may be attributed to Burstein-Moss effect in consequence of substitutional insertion of introduced Al^{3+} ions in spinel lattices.

Keywords: Magnesium aluminate spinel; Cation ratio; Gel combustion; Band gap.

1. Introduction

Studies on the stability of the spinel structured materials under high pressure, viz., pressure dependent phase transition in ZnAl_2O_4 and ZnGa_2O_4 have been performed in several works [1,2]. Room-temperature angle-dispersive x-ray diffraction measurements on spinel ZnGa_2O_4 upto 56 GPa shows two structural phase transition; one, at 31.2 GPa where ZnGa_2O_4 undergoes a transition from the cubic spinel structure to a tetragonal spinel structure and the other at 55 GPa where transition to the orthorhombic marokite structure (CaMn_2O_4 -type) takes place. Similarly, ab-initio study [3] on the high pressure

1
2
3 polymorphism of MgAl_2O_4 reveals the equilibrium pressures for the reactions of
4 formation/decomposition of the low pressure stable- $Fd3m$ to high pressure stable- $Cmcm$
5 type polymorphs to be ranging in the pressure of 0 to 60 GPa. According to the density
6 functional theory through LDA & B3LYP calculations, this polymorph transformation
7 takes place at 39 and 57 GPa, respectively. Owing to some excellent features of this stable
8 MgAl_2O_4 under ambient pressure like high melting point (2135°C), low thermal
9 conductivity, good thermal shock resistance, chemical inertness, and good mechanical
10 strength both at room temperature as well as high temperature, magnesium aluminate spinel
11 (MgAl_2O_4) has been used as refractory materials in steel ladles, vacuum induction furnaces
12 [4] etc. It is also ideal for use as insulating material [5], optical material [6], humidity
13 sensors [7], and photocatalyst activity [8]. Recent attraction of this material is for its use as
14 transparent window applications [9] in high performance sectors. There are several wet-
15 chemical processes those are currently used for the production of spinel powder at low
16 temperature and low cost, such as sol-gel [10], Pechini [11], co-precipitation [12], spray
17 drying [13], freeze drying [14] etc. Gel combustion method [15] is a self propagating
18 exothermic reaction route where the gel burst into smaller units and simultaneously
19 disintegrates into fine powder.

20
21
22 In this paper, we have aimed to prepare nanoscale magnesium aluminate spinel with
23 stoichiometric composition of magnesia (MgO) to alumina (Al_2O_3) as well as of different
24 alumina-richer compositions through gel combustion method. Influence of larger trivalent
25 to divalent cation content on the synthesis and optical property (viz. absorbance and band
26 gap) of all gel combusted powders was investigated.

23 24 25 **2. Experimental procedure**

26 27 28 **2.1. Materials and methods-**

29
30
31 Aluminium nitrate nonahydrate, [$\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$], magnesium nitrate hexahydrate
32 [$\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$], urea (Merck, India), formaldehyde solution [37% (w/v), Merck, India],
33 nitric acid (Merck, India) and ammonia solution (Merck, India), all of LR grade were used
34 as starting reagents. Methylol urea was first prepared by mixing urea with stoichiometric
35 amount of formaldehyde solution. Ammonia solution was used to make pH at 8.5 of the
36 mixture. The solution was kept overnight for proper digestion. Individual metal nitrates
37 were added in such an amount with methylol urea solution in order to prepare different
38 mole ratios of $\text{MgO} : x\text{Al}_2\text{O}_3$ (x is 1, 1.25, 1.5, 1.75, and 2). An additional lot of urea was

3 further dissolved with each solution to maintain metal ion to urea to formaldehyde solution
4 ratio as 1:2:4. HNO₃ was used to maintain the pH in acidic region. The homogeneous
5 solution looked as transparent. It was dried on hot plate at 120°C till it becomes viscous gel.
6 The gel becomes harder on further drying. Dried gel was ignited with a burning matchstick.
7 The combustion reaction took place vigorously with long flame and emission of flue gases.
8 Fluffy, porous, white and sometimes brownish coloured (due to presence of traces of
9 carbon) powder was produced for each composition. All the powders of all compositions
10 were subjected to heat treatment in a muffle furnace at 900°C.

17 **2.2. Characterizations-**

18 The morphology of powder was analyzed through field emission scanning electron
19 microscope (FESEM, Supra 35VP Carl Zeiss, Germany). The grain details were studied via
20 high resolution transmission electron microscopy (HETEM, TECNAI G2 30ST, FEI
21 Company, Netherlands). The absorption spectra was obtained from UV-Visible-NIR
22 absorption spectrometer (3600, Shimadzu, Japan) in electro-magnetic wave range of 200–
23 2000 nm. The optical band gap energy values for magnesium aluminate spinel containing
24 varied concentration of excess alumina (Al₂O₃) were determined through Tauc's relation
25 [16]: $(\alpha hv)^n = \text{constant}(hv - E_g)$ where hv is the photon energy, α is the absorption
26 coefficient, n is constant relative to the material. The dependence of the degree of
27 absorption related to the energy of the incoming photons (hv) varies with n equals to 2 for a
28 direct transition (E_g).

39 **3. Results and Discussions**

40 **3.1 Morphological study of powder-**

41 Fig. 1a-b shows the field emission scanning electron microscopic image for both $x=1$ &
42 1.75 varieties. The synthesized mass looked porous, fluffy, and loosely agglomerated. Fig.
43 1a indicates that the powder with $x=1$ composition comprises of mostly amorphous mass
44 occasionally coexisted with very few embedded nano particles. On the other hand, alumina-
45 richer ($x=1.75$) powder appeared in fully crystalline form of nearly spherical shaped nano
46 particles (Fig. 1b). This result is the indication of emission of gaseous components in large
47 volume, produced from combustion process that simultaneously inhibited probable
48 sintering among particles during the exothermic combustion reactions. The observed
49 discrepancies in development of crystallinity between different as-synthesized powders
50 may be clarified in the light of previous investigation. Earlier literature [17] suggests that
51
52

55
56
57
58
59
60

divalent cations preferentially crosslinks to the blocks of polymer gel structure in two dimensional pattern whereas the trivalent cations form stronger and stable networks with the polymer blocks in three dimensional manner. In the present case under study, gel containing stoichiometric composition of metallic ions (Mg^{2+} and Al^{3+}) dissociates into residues at comparatively much lower temperature, than the decomposition temperature of gels containing excess alumina compositions during combustion process. The comparative DTA graphs of three compositions are given in Fig. 2 in this context, which represents the dissociation temperatures of gels as $244^{\circ}C$ for $x=1.0$ rose to $288^{\circ}C$ for $x=2.0$. Expectedly, the low temperature exposure during cracking of gel containing stoichiometric metals- ratio is insufficient to form crystals. EDX pattern (Fig. 3) evidences well the phase purity of typical synthesized powder as the only peaks for elements like Mg, Al, and O have appeared.

Fig. 1: FESEM micrographs for as-synthesized: (a) $x=1$ & (b) $x=1.75$ compositions.

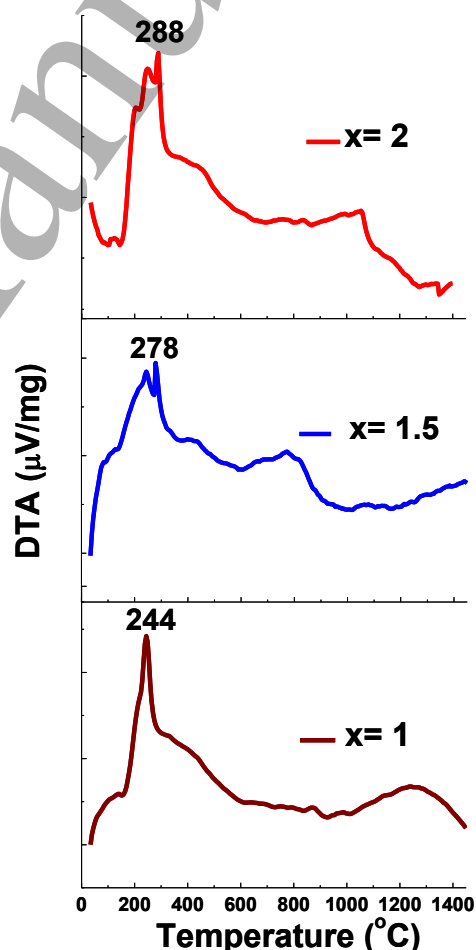

Fig. 2: Comparative study of DTA plots for dried gel containing varied trivalent to divalent cation ratio ($x=1, 1.5$ & 2 compositions).

Fig. 3: EDX pattern of $x=1.75$ composition.

The TEM- bright field image for the post synthesis heat treated $x=1$ composition has been presented in Fig. 4a which reveals the fact that the larger particles are consisted of finer sized grains. A representative similar image (Fig 4b) for $x=1.75$ composition puts up the impression that powders from all the compositions are similarly structured. Corresponding TEM dark field image of Fig 4a is given in Fig. 4c that reveals clearer view of grain structure through strongly illuminating nano-grains of nearly spherical shape and size in the range of 10-15 nm. The observation is consistent with that of FESEM. Literature suggests that magnesium aluminate spinel powder consisting of the grains in the size range of 100-250 nm could be obtained by conventional combustion method from the solution of aluminum nitrate, magnesium nitrate and urea only [18]. Contrary to that, as obtained in the present study, comparatively much smaller crystals points out the changed role of the fuel which is a combination of formaldehyde solution and urea in otherwise same sets of reagents as used in the earlier study. The indexed SAED pattern in Fig. 4d represents the bright diffraction rings made up of the tiny bright spots those originated through the convergence of reflecting waves from different lattice planes of clustered nano-grains. Arrangement pattern of diffracting rings proves the FCC structure [19] of synthesized $MgAl_2O_4$. High resolution TEM study (as in Fig. 4e) on the individual tiny grain shows the d-spacings between the adjacent lattice fringes. Lattice fringes in the image correspond to planes (044), (335) and (155). However, one notable point worth mentioning in this section

1
2
3 is that the trivalent to divalent cation ratio does not seem to have any observable influence
4 on the obtained grain shapes and sizes of synthesized powders of different compositions.

3.2 Optical studies-

3.2.1 Absorbance behavior:

Influence of excess alumina on the optical property of the studied magnesium aluminate spinel powders with different values of x was investigated through the measurements of their absorption property in the UV-Vis- NIR range. Absorbance spectra as presented in Fig. 5 indicates that the powder bearing excess alumina concentrations exhibit similar absorption edge but with progressive intensity. A magnified view of increasing capability of photon absorption in the UV range of 235-335 nm (5.27–3.70 eV) has been displayed in inset of Fig. 5. The absorption intensity is highest for alumina-rich $x=2$ and lowest for stoichiometric $x=1$ compositions. Absorption peak at 284 nm (4.36 eV) may be attributed to F^+ centre electron transition [20]. This high absorption capability at UV- regime suggests that synthesized powder can be considered for photocatalytic activities [21]. No absorption peak appears in the visible wavelength regime indicating the powders to be of highly reflective nature for visible lights. Apart from this, some broad but low intensity peaks have appeared in the NIR range that substantiates absorbing capability of the powder of NIR radiations.

Fig. 5: Absorption spectra of different powders with compositions ranging from $x=1$ to 2. Enlarged view of pattern is given in inset.

3.2.2 Band gap:

Band gap values have been evaluated based upon the obtained data from the absorbance spectra of heat treated stoichiometric ($x=1$) as well as alumina richer compositions ($x=1.25$

1
2
3 to 2). Considering a direct band gap [22] of this material, the Tauc's plot for all
4 compositions has been presented in Fig. 6a-e, respectively. The estimated band gap for $x=1$
5 is 3.01 eV and the value increases progressively up to 5.21 eV for $x=2$. The error of
6 measurement lies within the range of ± 0.077 . Fig. 7 represents the estimated band gap
7 values of concerned materials, establishing the increasing trend with increasing excess
8 alumina concentrations. Similar result of enhancement in band gap was also found by
9 previous researchers [21] where magnesium aluminate spinel was produced via solid state
10 reaction method using MgO and Al₂O₃ powders. Other studies [23,24] on optical properties
11 of the spinel oxides were done by following the First principle calculations within the
12 generalized gradient approximation of the density functional theory while the full-potential
13 linearized augmented plane wave method was used with the generalized gradient
14 approximation. It was seen in case of Mg doped ZnAl₂O₄ system (Mg_xZn_{1-x}Al₂O₄) that the
15 band gap increases from 3.851 eV to 5.079 eV with increasing doping insertion. This can
16 be explained by the threshold of the electronic transition from O-2p to the empty Mg-3p
17 electron states due to the substitution of Zn with Mg. Recently Tauc's relation has also been
18 utilized in describing the change in band gap, widening followed by collapsing under high
19 pressure compression in case of semiconductors like InVO₄, InNbO₄, and InTaO₄ [25].

21
22
23
24
25
26
27
28
29
30
31
32
33

34
35 In some of the semiconductor systems like Sn doped In₂O₃ [26] or Al doped ZnO [27]
36 materials, increase in band gap have been observed. Following Pauli's principle for
37 avoiding double occupation, the associated electrons of the doped ions occupy the bottom
38 of the conduction band in a form of electron gas and block the lowest energy transitions.
39 Due to this reason such shifting in band gap occurs, known as Burstein-Moss effect [28]. In
40 the present study, accommodation of excess aluminium in the spinel lattice takes place by
41 incorporation of the trivalent aluminium ions by replacing tetrahedral divalent magnesium
42 ions [29]. Electrochemical imbalance that arises out of insertion of excess positive charge
43 results in subsequent charge neutrality through formation of cation vacancies related to
44 magnesium/aluminium ions as well as possible anionic vacancies. Electrical charge balance
45 may be maintained by two ways- (1) addition of two substituting Al³⁺ ions is electrically
46 compensated by creating vacancy of one tetrahedral Mg²⁺ ion; (2) addition of three
47 substituting Al³⁺ ions are compensated by one of octahedral Al³⁺ ion vacancy along with
48 one oxygen diffusion interstitials. The large trivalent cation doping in the present case could
49 presumably simulate the situation aroused in the previous case [27] and becomes
50
51
52
53
54
55
56
57
58
59
60

responsible for the Burstein-Moss effect to take place. The widening in band gap therefore follows the concentration of the trivalent doping.

4. Conclusions

Magnesium aluminate spinel ($\text{MgO} \cdot x\text{Al}_2\text{O}_3$) compositions along line of homogeneity with different values of x starting from 1 and ranging up to 2 were produced by urea-formaldehyde-fuelled gel combustion method. Trivalent cations, through a change in gel structure, affect the combustion temperature and subsequently the crystallinity of the produced powder. However, it does not possibly influence the grain sizes. Intensity of absorption spectra as obtained in UV-region increases with excess alumina concentration. The increase in trivalent to divalent cation ratio induces widening of energy band gap value from 3.01 eV for $x=1$ to 5.21 eV for $x=2$ compositions due to Burstein-Moss effects. Absorption study reveals that the synthesized powders are suitable for application in photocatalytic reactions.
